Batched prime pair-table construction

Measured engineering result. Frozen protocol commit `a45880095`; session `ECBS1h4d0b9e4a02a7` from clean source commit `3904a4f9`. The registered curve is `icv1-fp20-t727-cd198a38`, subgroup order 562427. Eight fresh public targets, three measured rounds per arm.

Arm	Verified	Mean cold GAE	Mean setup wall
scalar table	24/24	18,633.042	243.226 µs (L0)
batched table	24/24	18,633.042	128.380 µs (L0)
rho.negation	24/24	1,148.125	—
rho A/A	24/24	1,148.125	—

The batched builder uses one field inversion per abscissa row. At B=64, the source loops imply 64 versus 4,096 inversions for the scalar table. These are derived primitive counts. The focused test found the exact same table map and counted additions on a generated prime fixture; the sealed session's mechanical checker found **32/32 exact paired outputs and counted phases**, including warmups. The paired counted-GAE quotient is 1.000.

Full local replay reproduced all 96 measured executions with zero integrity problems. The matched batch/rho counted quotient is 16.229 (95% target-cluster interval 12.975–20.964). Mean setup wall is smaller in the batch arm, but all runs earned L0 and the whole-solve comparison admitted zero wall pairs. Native work remains partly unpriced, so this figure establishes neither a complete-cost nor whole-solve runtime gain.

Evidence: `REPORT.md`, `phase-metrics.json`, `pair-check.json`, `replay-all.json`, `sessions/prime20-b64-batchtable/`, and `render_chart.mjs`. No canonical frontier graph changes.
